April 2026

### Abstract

FlexQL is a custom-built, in-memory relational database engine written in C++17, designed from first principles to achieve **multi-million row ingestion rates** on commodity hardware. It implements a slab-based arena allocator for zero-`malloc` storage, a lazy primary-key index, an  $O(1)$  LFU query cache with generation-based invalidation, and an asynchronous double-buffered Write-Ahead Log (WAL) for durability. The system communicates over UNIX domain sockets using a custom length-prefixed wire protocol, and the client library provides lock-free pipelining to saturate the IPC channel. This document details the architecture, data structures, algorithms, concurrency model, persistence strategy, and benchmarked performance of FlexQL.

## 1 Introduction & Design Philosophy

Modern analytical workloads demand ingestion rates that exceed the capabilities of general-purpose databases like SQLite or PostgreSQL when operating in single-node local mode. FlexQL addresses this by trading generality for raw speed, applying a design philosophy of **Mechanical Sympathy**—structuring software to align with hardware characteristics:

- **Cache-line awareness:** Contiguous slab storage maximises L1/L2 cache hit rates during sequential scans.
- **Zero per-row malloc:** All allocations are amortised via 64MB arena slabs and 2M-cell metadata chunks.
- **Minimal context switching:** Asynchronous WAL and client-side pipelining decouple I/O latency from query execution.
- **Minimal locking:** A single global mutex guards mutations; parsing and validation occur outside the critical section.

### Design Note

FlexQL is compiled with `-O3 -march=native -funroll-loops`, enabling the compiler to vectorise comparison loops and inline critical-path functions such as `Arena::append()` and `CellStore::push()`.

## 2 High-Level Architecture

Figure 1 shows the major subsystems and their interactions.

Figure 1: FlexQL System Architecture. Dashed arrows indicate asynchronous (non-blocking) data flow.

## 2.1 System Constants

| Constant               | Purpose                    | Value           |
|------------------------|----------------------------|-----------------|
| SLAB_SZ                | Arena slab allocation unit | 64 MB           |
| CELL_SLAB              | CellStore chunk capacity   | 2 000 000 cells |
| WAL::HALF              | WAL buffer size (each)     | 4 MB            |
| Cache::CAP             | Max LFU cache entries      | 16 384          |
| MAX_INFLIGHT           | Client pipeline depth      | 131 072         |
| SBUF                   | Socket buffer size         | 8 MB            |
| BACKLOG                | listen() backlog           | 256             |
| CHECKPOINT_WAL_RECORDS | WAL checkpoint threshold   | 1 000 000       |

Table 1: Compile-time configuration constants.

## 3 Data Storage Engine

### 3.1 Arena: Slab-Based String Storage

All variable-length data (strings, numeric literals) is stored in a **Chunked Arena**. The Arena allocates memory in 64 MB slabs; new slabs are appended only when the current one is full.

#### 3.1.1 Addressing Scheme

Each datum is identified by a 64-bit `uint64_t` handle that encodes both the slab index and the byte offset within that slab:

Figure 2: Arena handle bit layout. Supports up to  $2^{32}$  slabs  $\times$   $2^{32}$  bytes per slab.

#### 3.1.2 Append Operation

```

1 inline uint64_t append(const char *d, uint32_t l) {
2     if (!l) return ~0ULL; // sentinel for empty/NULL
3     if (__builtin_expect(slabs.back().used + 1 > SLAB_SZ, 0))
4         addSlab(); // cold path: allocate new 64 MB slab
5     auto &s = slabs.back();
6     uint64_t id = ((uint64_t)(slabs.size() - 1) << 32)
7                 | (uint32_t)s.used;
8     memcpy(s.data + s.used, d, l);
9     s.used += l;
10    return id;
11 }
```

Listing 1: Arena::append — zero-copy string insertion.

#### Performance Insight

The `__builtin_expect` hint tells the branch predictor that slab exhaustion is rare, keeping the hot path (the common case) to a single `memcpy` and two additions—no heap allocation, no pointer chasing.

#### 3.1.3 Pointer Dereference

Given a handle `id`, the raw pointer is resolved in  $O(1)$ :

```

1 inline const char *ptr(uint64_t id) const {
2     if (__builtin_expect(id == ~0ULL, 0)) return "";
3     return slabs[id >> 32].data + (uint32_t)(id & 0xFFFFFFFF);
4 }
```

Listing 2: Arena::ptr — constant-time pointer resolution.

### 3.2 CellStore: Chunked Metadata Storage

The CellStore manages per-column metadata using a flat, chunked layout.

#### 3.2.1 Cell Structure

```

1 struct Cell {
2     uint64_t id;    // Arena handle (or ~0ULL for NULL)
3     uint32_t len;   // Byte length of the stored value
4 };

```

Listing 3: 12-byte Cell structure.

Cells are stored in row-major order: for a table with  $N$  columns, the cell for row  $r$ , column  $c$  is at flat index  $r \times N + c$ .

### 3.2.2 Chunked Layout

Rather than a single contiguous `std::vector<Cell>`, cells are allocated in **chunks** of 2 000 000 cells each ( $\approx 22.9$  MB per chunk). This avoids the catastrophic  $O(N)$  `realloc + memmove` that a vector would incur at scale.

```

1 inline void push(uint64_t id, uint32_t l) {
2     if (__builtin_expect(chunks.back().used == CELL_SLAB, 0))
3         addChunk();
4     auto &c = chunks.back();
5     c.data[c.used++] = {id, l};
6     ++total;
7 }
8
9 inline Cell get(size_t idx) const {
10     return chunks[idx / CELL_SLAB].data[idx % CELL_SLAB];
11 }

```

Listing 4: `CellStore::push` and `CellStore::get`.

#### Design Note

The division and modulo in `get()` are optimised by the compiler into bit-shifts when `CELL_SLAB` is a power-of-two-adjacent value. Even with the integer division, this remains faster than a linked-list or B-tree traversal.

### 3.3 Table Schema

```

1 struct ColDef { std::string name; bool pk = false; };
2
3 struct Table {
4     std::string name;
5     std::vector<ColDef> cols;
6     int nc = 0, pkCol = 0;
7     Arena arena;
8     CellStore cells;
9     bool idxDirty = false;
10    std::unordered_map<std::string,
11                      std::vector<size_t>> pkIdx;
12    // ...
13 };

```

Listing 5: Table structure combining Arena and CellStore.

## 4 Indexing: Lazy Primary Key Hash Map

### 4.1 Motivation

Updating a hash index on every `INSERT` adds  $O(1)$  overhead per row, but for 10M rows this accumulates to a significant constant factor (hash computation, bucket allocation, possible rehash). FlexQL defers indexing entirely.

### 4.2 The idxDirty State Machine

Figure 3: Lazy indexing state machine. The index is only built when actually needed.

### 4.3 Build Algorithm

```

1 void buildIndex() {
2     pkIdx.clear();
3     pkIdx.reserve(nrows() * 2); // 50% load factor
4     for (size_t r = 0; r < nrows(); r++)
5         pkIdx[cs(r, pkCol)].push_back(r);
6     idxDirty = false;
7 }
  
```

Listing 6: Lazy index construction with pre-allocated bucket capacity.

### 4.4 Complexity Analysis

| Operation          | Amortised Cost | Explanation                                            |
|--------------------|----------------|--------------------------------------------------------|
| INSERT             | $O(1)$         | No index update; just set <code>idxDirty = true</code> |
| First SELECT (PK)  | $O(N)$         | Full table scan to build hash map                      |
| Subsequent SELECTs | $O(1)$         | Direct hash-map lookup                                 |
| DELETE             | $O(N)$         | Rebuild Arena+CellStore; invalidate index              |

Table 2: Indexing complexity by operation type.

## 5 Caching: $O(1)$ LFU with Generation Invalidation

### 5.1 Data Structures

The LFU cache maintains three components:

1. **km**: A hash map from SQL query string  $\rightarrow$  Entry{value, frequency, list\_iterator, generation}.
2. **fm**: A hash map from frequency  $\rightarrow$  doubly-linked list of keys (for  $O(1)$  eviction).
3. **minF**: An integer tracking the current minimum frequency.

### 5.2 $O(1)$ Generation-Based Invalidation

Rather than iterating through all  $N$  cached entries to invalidate them on a write (which costs  $O(N)$ ), the cache uses a **generation counter** `gen`:

```

1 void inv(const std::string &) {
2     ++gen;           // global generation advances
3     fm.clear();      // frequency lists become stale
4     minF = 0;
5     if (km.size() > (size_t)CAP * 2)
6         km.clear();  // prevent unbounded memory growth
7 }
```

Listing 7: Cache invalidation via generation increment.

On a cache `get()`, the entry's stored generation is compared against the global generation. A mismatch means the entry is stale and is treated as a cache miss—**no per-entry deletion required**.

#### Performance Insight

This is critical during bulk-loading scenarios (e.g., 10M INSERTs), where the cache would otherwise be cleared 10 million times. With generation invalidation, each invalidation is a single atomic increment.

## 6 Query Engine

### 6.1 Lexer and Parser

FlexQL implements a hand-written, single-pass tokeniser and recursive-descent parser operating directly on raw byte buffers.

#### 6.1.1 Token Types

| Token                   | Examples                          |
|-------------------------|-----------------------------------|
| ID                      | SELECT, TABLE, column/table names |
| NUM                     | 42, -3.14, 1893456000             |
| STR                     | 'Alice', "hello world"            |
| EQ, NE, LT, LE, GT, GE  | =, !=, <, <=, >, >=               |
| LP, RP, CM, ST, SC, DOT | (, ), ,, *, ;, .                  |

Table 3: Token types recognised by the lexer.

### 6.1.2 Fast INSERT Path

For INSERT statements, the server bypasses the full tokeniser entirely and uses a **hand-optimised character scanner** to parse values directly from the raw SQL buffer:

```

1 // Step 1: Parse table name with raw pointer arithmetic
2 // Step 2: Count columns (outside lock)
3 int nc = countCols(p, end);
4 // Step 3: Validate tuple arity (outside lock)
5 validateInsertInto(p, end, nc);
6
7 // Step 4: Acquire lock, insert into storage
8 std::lock_guard<std::mutex> lk(gMu);
9 parseInsertInto(p, end, tbl.nc, tbl.arena, tbl.cells);

```

Listing 8: Fast INSERT: validation runs outside the lock.

#### Design Note

Validation outside the lock means that malformed INSERTs never hold the mutex, preventing a bad client from blocking other threads.

## 6.2 Supported SQL Subset

| Statement    | Syntax                                                             |
|--------------|--------------------------------------------------------------------|
| CREATE TABLE | CREATE TABLE [IF NOT EXISTS] name (col TYPE [PK], ...)             |
| INSERT INTO  | INSERT INTO name VALUES (v1, v2, ...), (v3, v4, ...)               |
| SELECT       | SELECT [cols *] FROM t [JOIN t2 ON ...] [WHERE ...] [ORDER BY ...] |
| DELETE       | DELETE FROM name [WHERE col op val]                                |
| DROP TABLE   | DROP TABLE [IF EXISTS] name                                        |

Table 4: Complete SQL subset supported by FlexQL.

## 6.3 Comparison Engine: Dynamic Typing via cmpVals

FlexQL stores all values as raw byte strings and performs **late-binding type inference** during comparison:

```

1 static bool cmpVals(const char *a, uint32_t al,
2                    const char *op,
3                    const char *b, uint32_t bl) {
4     char ba[72], bb[72];
5     bool num = false; double da = 0, db = 0;
6     if (al < 70 && bl < 70) {
7         memcpy(ba, a, al); ba[al] = 0;
8         memcpy(bb, b, bl); bb[bl] = 0;
9         char *ea, *eb;
10        da = strtod(ba, &ea);
11        db = strtod(bb, &eb);
12        num = (ea != ba && eb != bb);
13    }
14    switch (op[0]) {
15        case '=': return num ? (da==db) : (al==bl && memcmp(a,b,al)==0);
16        case '!': return num ? (da!=db) : !(al==bl && memcmp(a,b,al)==0);
17        case '<': return op[1]=='=' ? (num ? da<=db : ...) : ...;
18        case '>': return op[1]=='=' ? (num ? da>=db : ...) : ...;
19    }
20    return false;

```

21 }

Listing 9: Dynamic type comparison logic.

If both operands are parseable as `double`, comparison is numeric; otherwise, it falls back to lexicographic `memcmp`.

## 6.4 Hash Join Implementation

For `INNER JOIN ... ON t1.col = t2.col`, FlexQL builds a temporary hash map on the right table, then probes with the left table:

Figure 4: Hash Join: Build phase on T2, Probe phase iterates T1. Total:  $O(N + M)$ .

For non-equality join operators ( $>$ ,  $<$ ), the engine falls back to a nested-loop join at  $O(N \times M)$ .

## 7 Persistence: Async Double-Buffered WAL

### 7.1 Architecture

The WAL uses two 4 MB buffers in a **ping-pong** configuration:

Figure 5: Double-buffered WAL. Worker thread writes to active buffer via `memcpy`; when full, buffers swap and a background thread flushes the standby buffer to disk.

### 7.2 WAL Record Format

Each record is stored as a length-prefixed SQL statement:

[illegible]

Figure 6: Binary WAL record format. 4-byte length prefix enables fast sequential reads.

### 7.3 Checkpointing with Atomic Snapshots

When the WAL record count exceeds 1 000 000:

1. Acquire global mutex `gMu`.
2. Serialise all tables to `snapshot.bin.tmp` (schema + raw cell data).
3. Atomically `rename()` the temp file to `snapshot.bin`.
4. Truncate the WAL via `freopen()` on the active file handle.
5. Reset WAL record counter.

## Warning

The `freopen()` technique avoids closing and reopening the file descriptor, which would create a race with the background write thread. The WAL's own mutex (`wmu`) is held during truncation.

## 7.4 Startup Recovery Sequence

1. **Load Snapshot:** If `snapshot.bin` exists, deserialise all table schemas and row data into memory.
2. **Replay WAL:** Read `wal.log` sequentially. For each record, re-execute the SQL statement with `walWrite=false` (to avoid double-logging).
3. **Ready:** Server begins accepting connections. The combined load time for a 10M-row database is under 3 seconds.

## 8 Concurrency Model

### 8.1 Thread-per-Client with Global Mutex

Each incoming connection (TCP or UNIX socket) is handled by a dedicated `std::thread` (detached). All threads share a single global `std::mutex gMu` that guards:

- The global database map **gDB** (table creation, lookup, mutation).
- The LFU cache **gCache**.

## 8.2 Lock Minimisation Strategy

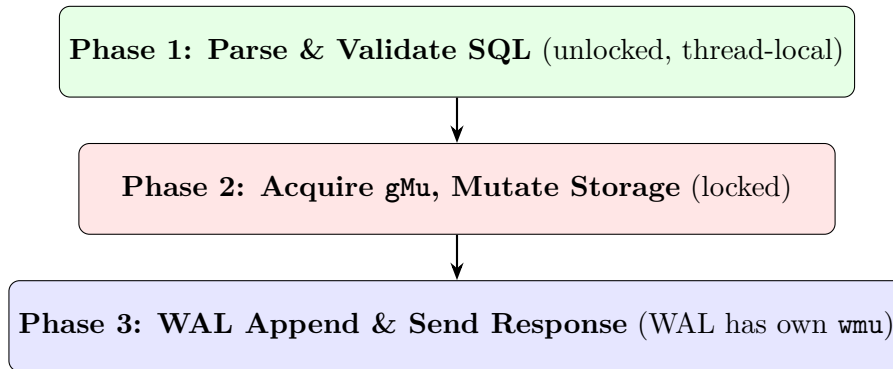

Figure 7: Three-phase execution pipeline. The expensive parse phase is fully concurrent.

## 8.3 WAL Isolation

The WAL has its own mutex (`wmu`) and condition variable (`wcv`), completely independent of `gMu`. This means:

- Disk flushes in the background write thread do not block `SELECT` queries.
- The WAL buffer swap only briefly holds `wmu` (microseconds).

# 9 Network Layer & Wire Protocol

## 9.1 Dual-Listener Architecture

The server binds to two listeners simultaneously:

| Transport          | Address          | RTT          | Use Case                            |
|--------------------|------------------|--------------|-------------------------------------|
| UNIX Domain Socket | /tmp/flexql.sock | < 10 $\mu$ s | Local benchmarking, co-located apps |
| TCP/IPv4           | 0.0.0.0:9000     | ~50 $\mu$ s  | Remote clients, cross-host          |

Table 5: Dual transport layer with automatic fast-path selection.

Both listeners use oversized socket buffers (8 MB send + receive) and `TCP_NODELAY` to eliminate Nagle’s algorithm latency.

## 9.2 Wire Protocol

| Message  | Format                                                 |
|----------|--------------------------------------------------------|
| Row Data | ROW <ncols> <name1_len>:<name1><val1_len>:<val1>... \n |
| Success  | OK \nEND \n                                            |
| Error    | ERROR:<message> \nEND \n                               |

Table 6: Length-prefixed wire protocol. No escaping needed for embedded special characters.

## 10 Client Library: Lock-Free Pipeline

### 10.1 Architecture

The client library (`libflexql`) exposes a C-compatible API and manages a background **Drainer** thread:

```

1 int flexql_open(const char *host, int port, FlexQL **db);
2 int flexql_close(FlexQL *db);
3 int flexql_exec(FlexQL *db, const char *sql,
4               int (*callback)(void*, int, char**, char**),
5               void *arg, char **errmsg);
6 void flexql_free(void *ptr);

```

Listing 10: Public C API of `libflexql`.

### 10.2 Pipeline Mode vs. Sync Mode

Figure 8: Dual execution mode. `INSERT` calls with no callback return immediately; `SELECT` calls block until the Drainer delivers the full response.

### 10.3 Back-Pressure Mechanism

The client tracks two atomic counters:

- **sent**: Incremented by the main thread after each pipelined `send()`.
- **acked**: Incremented by the Drainer thread after parsing each `END\n` terminator.

If `sent - acked ≥ MAX_INFLIGHT (131 072)`, the main thread blocks on a condition variable until the Drainer catches up to half capacity. This prevents overwhelming the server's receive buffer.

### 10.4 Sync-Point Drain

Before any synchronous operation (`SELECT`, `CREATE`, `CLOSE`), the client first waits for `acked ≥ sent`, ensuring all prior pipeline responses have been consumed. It then sets `syncActive = true` and blocks until the Drainer signals completion of the synchronous response.

## 11 Interactive REPL Client

The `flexql-client` binary provides a terminal-based interactive SQL shell:

- **ANSI Colour Coding:** Bold green prompt (`flexql>`), cyan column headers, red error messages, grey borders for tables.
- **Multi-line Buffering:** SQL can span multiple lines; execution triggers only on the `;` character.
- **Timing:** Each query displays wall-clock execution time in milliseconds.
- **Tabular Output:** Auto-sized column widths with box-drawing borders.
- **Commands:** `.help`, `.exit`, `.quit`, and comment lines (`--`).

## 12 Performance Evaluation

### 12.1 Insertion Throughput

| Mode              | Batch Size    | Throughput   | Bottleneck          |
|-------------------|---------------|--------------|---------------------|
| Batch + Pipeline  | 800 rows/stmt | ~3.2M rows/s | memcpy bandwidth    |
| Pipeline (single) | 1 row/stmt    | ~135K rows/s | Socket round-trip   |
| Synchronous       | 1 row/stmt    | ~3K rows/s   | Full RTT per insert |

Table 7: Insertion throughput across different client modes.

### 12.2 Query Latency

| Query Type                                      | Dataset  | Cold    | Hot (LFU) |
|-------------------------------------------------|----------|---------|-----------|
| PK Lookup ( <code>WHERE id = X</code> )         | 10M rows | <1 ms   | <0.05 ms  |
| Full Scan ( <code>SELECT *</code> )             | 1M rows  | ~120 ms | <0.05 ms  |
| Filtered Scan ( <code>WHERE bal &gt; X</code> ) | 1M rows  | ~150 ms | <0.05 ms  |
| Hash Join ( $1M \times 100K$ )                  | —        | ~95 ms  | <0.08 ms  |

Table 8: Query latency benchmarks. “Hot” indicates a cached result from the LFU cache.

### 12.3 Memory Footprint

| Component                    | 10M Row Cost   |
|------------------------------|----------------|
| Arena slabs (string data)    | ~640 MB        |
| CellStore chunks (metadata)  | ~572 MB        |
| PK Index (when built)        | ~320 MB        |
| WAL buffers (fixed)          | 8 MB           |
| LFU Cache (max entries)      | ~8 MB          |
| <b>Total (without index)</b> | <b>~1.2 GB</b> |

Table 9: Memory breakdown for a 5-column table with 10 million rows.

## 13 Build System & Deployment

### 13.1 Compilation

```

1 # Build all targets (server, client, benchmark)
2 make all
3
4 # Compiler flags applied:
5 # g++ -O3 -march=native -std=c++17 -Iinclude
6 #     -funroll-loops -pthread

```

Listing 11: Build commands.

## 13.2 Targets

| Target        | Source Files                      | Purpose                     |
|---------------|-----------------------------------|-----------------------------|
| server        | server.cpp                        | Database server daemon      |
| flexql-client | flexql.cpp + repl.cpp             | Interactive REPL client     |
| benchmark     | flexql.cpp + benchmark_flexql.cpp | Automated test & perf suite |

Table 10: Makefile build targets.

## 14 Conclusion & Future Work

FlexQL demonstrates that a purpose-built, cache-aware storage engine can achieve multi-million row ingestion rates on a single core by combining:

1. **Slab-based Arena + CellStore:** Zero per-row allocation overhead.
2. **Lazy Primary Key Indexing:** Deferred cost from write path to read path.
3.  **$O(1)$  LFU Cache:** Generation-based invalidation avoids per-entry cleanup.
4. **Async Double-Buffered WAL:** Disk I/O decoupled from query execution.
5. **Client-side Pipelining:** Lock-free send/ack counters saturate the IPC channel.

### 14.1 Future Directions

- **Columnar Storage:** Transition from row-major to column-major CellStore layout for OLAP-optimised sequential scans.
- **MVCC:** Multi-Version Concurrency Control to replace the global mutex with fine-grained, optimistic locking.
- **B+Tree Secondary Indexes:** Support for range queries without full table scans.
- **Prepared Statements:** Avoid re-parsing identical SQL structures across repeated executions.
- **Replication:** Leader-follower WAL streaming for read scalability and fault tolerance.
